#### **Preface**

This document comprises the National Oceanic and Atmospheric Administration (NOAA) National Environmental Satellite, Data, and Information Service (NESDIS), Office of Satellite and Product Operations (OSPO), publication of this Enterprise Land Surface Emissivity Algorithm Theoretical Basis Document. This document reflects current operations for the DOC/NOAA/NESDIS Environmental Satellite Processing Center (ESPC) (NOAA5045) information technology systems. This document describes the established ESPC procedure for Enterprise Land Surface Emissivity users in accordance with Federal, DOC, NOAA, NESDIS and OSPO requirements.

The published version of this document can be found at the OSPO SharePoint Products Library.

#### 1 INTRODUCTION

In this section, the background and requirement of the land surface emissivity (LSE) product will be introduced along with satellite instrument descriptions. Section 2 provides detailed description of the LSE retrieval algorithm and operations concept including the algorithm theoretical basis, processing outline, input/output data, error budget and practical considerations during the operation. Finally, validation strategies and preliminary results are provided. Assumptions and limitations associated with the algorithm are discussed in Section 3. Finally, Section 4 lists the references cited.

#### 1.1 Product Overview

#### 1.1.1 Product Description

Land surface temperature (LST) as an important proxy of surface energy is required in a wide variety of applications of hydrology, meteorology and climatology (Wan and Dozier 1996, Yu et al. 2005). Remote sensing is a unique approach which allows global and regional coverage for LST. Many algorithms have been proposed to retrieve LST from thermal infrared (TIR) observations (Dash et al. 2002, Li et al. 2013), in which temperature coupled with LSE and atmospheric downward radiance. From the perspective of emissivity, these methods could be roughly classified into two types: LST retrieval with known LSE, such as split window (SW) algorithm and single-channel algorithm (Wan and Dozier 1996, Jiménez-Muñoz 2003), and simultaneous temperature and emissivity separation (Wan and Li 1997, Gillespie et al. 1998). The latter one requires more temporal or spectral information. For sensors with only one or two TIR channels, emissivity is an important input and its variation is still the biggest impediment in satellite LST retrieval (Becker 1987, Qin et al. 2001, Yu et al. 2008). Besides, as an intrinsic property of the surface, broad band emissivity is important for the precise determination of longwave radiative energy, and this is particularly necessary for arid/semi-arid regions, where LSE deviate considerably from the behavior of black body. Satellite LST&E have been assimilated into climate, atmospheric and land surface models and high-quality LSE has demonstrated its significant contribution (Jin and Liang 2006, Vogel et al. 2011).

The Joint Polar Satellite System (JPSS) and the Geostationary Operational Environmental Satellites R Series (GOES-R) are the nation's next generation of the polar-orbiting environmental satellites and geostationary weather satellites, respectively. The Visible Infrared Radiometer Suite (VIIRS) onboard JPSS series and the Advanced Baseline Imager (ABI) onboard GOES-R will play an important role in developing LST records. The new proposed LSE product will enhance LST production of JPSS and GOES-R missions as well as to support forecasting models. In the United States of America, demands of satellite LSE data are from a variety of government agencies as well as from universities and research institutes.

Version 1.4

February 2025

#### 1.1.2 Product Requirements

LSE product is primarily designed to support LST product. To meet the requirement of LST accuracy, we define LSE product requirement according to current algorithm performance and the input data quality. The individual requirements for each satellite missions along with the broad band are listed in Table 1-1.

Table 1-1 LSE Ploduct Requirement						
	VIIRS	ABI	Broadband			
Spatial Coverage	Global Gridded	Global Gridded	Global Gridded			
Spectral Coverage	M15(10.26–11.26 μm) M16(11.54–12.49 μm)	Ch14(10.8-11.6 µm) Ch15(11.8-12.8 µm)	8-13.5 μm			
LSE Accuracy	0.01	0.01	0.015			
LSE Precision	0.015	0.015	0.02			
Data Range	0-1	0-1	0-1			
Refresh Rate	Daily	Daily	Daily			
Horizontal resolution	0.009×0.009 degree	0.009×0.009 degree	0.009×0.009 degree			
Mapping Uncertainty	3 sigma of 1 km	3 sigma of 1 km	3 sigma of 1 km			

Table 1-1 LSE Product Requirement

#### 1.2 Satellite Instrument Description

VIIRS onboard S-NPP and future JPSS series satellites collect visible and infrared imagery and radiometric measurements of the land, atmosphere, cryosphere, and oceans. It is a new generation of operational moderate resolution-imaging instrument following the legacy from the Advanced Very High-Resolution Radiometer (AVHRR) on NOAA family of polar orbiting platforms and the Moderate Resolution Imaging Spectroradiometer (MODIS) on Terra and Aqua satellites. Based on VIIRS data, many critical environmental products are generated, including snow and ice cover, clouds and aerosols properties, ocean color, sea and land surface temperature, vegetation health and surface albedo. These variables greatly benefit the operational weather community towards a more precise prediction of weather, flooding, and storm, etc.

VIIRS provides global moderate-resolution data twice a day without any gap. It is a scanning radiometer with a total field of view of 112.56° in the cross-track direction. The swath width is about 3060 km at a nominal equatorial altitude of 829 km, providing full global daily coverage in both daytime and nighttime. Its 22 spectral bands, from 0.4 to 12.5µm (Table 1-2), provide data for the production of more than 20 Environmental Data Records (EDRs). There are 16 moderate-resolution bands (M bands, each with 16 detectors) with a spatial resolution of 750m at nadir, five imaging resolution bands (I band, each with 32 detectors) with a 375m spatial resolution at nadir, and one panchromatic DNB with a near constant 750m spatial resolution throughout the scan. The M bands include 11 reflective solar bands (RSB) and 5 thermal emissive bands (TEB) which

Version 1.4

February 2025 2

includes the two split window channels used for LST retrieval, and the I-bands include 3 RSB and 2 TEB (Cao et al., 2013). Detailed spectral characteristics are summarized in Table 1-2.

Table 1-2 Spectral Characteristics of VIIRS

ABI is the primary instrument on the GOES-R Series observing the earth's weather, oceans, and environment. It is a multi-channel passive imaging radiometer designed to observe the western hemisphere with multiple spatial domains. The instrument has two scan modes; the default mode concurrently takes a full disk (FD) image every 15 minutes, a Continental U.S. (CONUS) image every five minutes, and two meso-scale images every 60 seconds. ABI can also operate in continuous FD mode, providing uninterrupted FD scans every 5 minutes. ABI views the Earth with 16 different spectral bands, including two visible channels, four near-infrared channels, and ten infrared channels. Its spatial resolution is nominally 2 km for the infrared bands and 0.5 km for the 0.64µm visible band (Schmit et al., 2007). More details are provided in Table 1-3.

ABI is used in a wide range of applications related to weather, oceans, land, climate and hazards (fires, volcanoes, floods, hurricanes and storms that spawn tornadoes). It tracks

Version 1.4

February 2025

and monitors cloud information, atmospheric motion, convection, land surface temperature, ocean dynamics, flow of water, fire, smoke, volcanic ash plumes, aerosols and air quality, and vegetative health. ABI's data enables meteorologists to pinpoint and track developing storms in much greater detail. Benefits from the ABI include improved tropical cyclone forecasts, fewer weather-related flight delays and airline incidences with volcanic plumes, improved production and distribution of electricity and natural gas, increased efficiency in irrigated water usage in agriculture, and higher protection rates for recreational boats in the event of a tropical storm or hurricane.

#### 2 ALGORITHM DESCRIPTION

#### 2.1 Processing Outline

LSE product is generated based on the vegetation cover method (VCM), which combines two constant emissivity values of the bare ground and full vegetation situations of each pixel. The real time emissivity is adjusted according to the green vegetation fraction (GVF) and the snow fraction. The processing includes two parts as figure 2-1 shows: the static emissivity module aims to generate background component. Emissivity climatology served as the bare component in the algorithm, and the dynamic emissivity module accounts for the emissivity variation due to GVF and snow fraction.

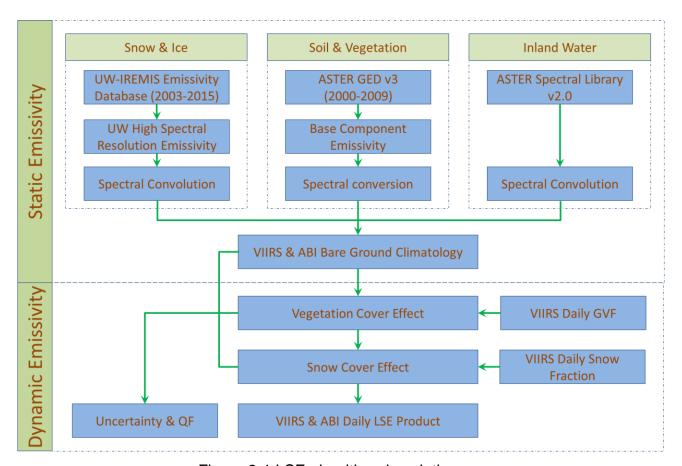

Figure 2-1 LSE algorithm description

In the static emissivity module, land surface is classified into three types with different processing approaches according to their thermal emission characteristics. The permanent snow & ice emissivities are directly converted from the mean value of a long term MODIS emissivity product; the values of the inland water are determined according to Advanced Space borne Thermal Emission and Reflection Radiometer (ASTER) spectral library dataset, and those of soil and vegetation area, also the most common

Version 1.4

February 2025 5

surfaces, are derived from the ASTER Global Emissivity Dataset (GED) dataset and the corresponding mean normalized difference vegetation index (NDVI) using the reverse form of the VCM. More details are given in the section 2.3.

VIIRS/ABI bare ground emissivity climatology, VIIRS GVF and snow fraction are used in the dynamic emissivity module to derive the daily emissivity and its associated quality flags to determine the data quality. The dynamic LSE processing flowchart is demonstrated in Figure 2-2.

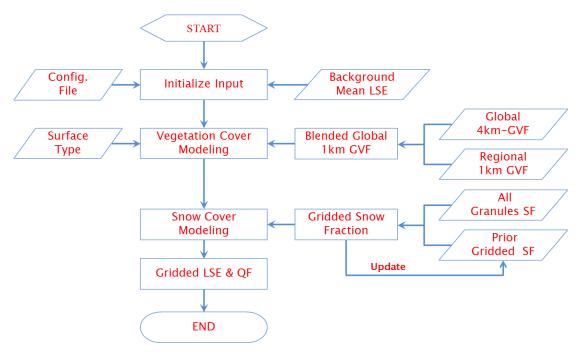

Figure 2-2 LSE Processing Flowchart

#### 2.2 Algorithm Input

This section describes the input needed to process the LSE product. Both the VIIRS and ABI LSE use VIIRS EDR products as primary input to account for the dynamic change. Apart from the satellite product, LSE algorithm requires the ancillary data such as bare ground emissivity and the look-up table, in which VIIRS and ABI have specific data designed for certain channel.

#### 2.2.1 Derived sensor data

There are three types of derived data from VIIRS: VIIRS GVF, VIIRS annual surface type and VIIRS snow fraction.

Currently, VIIRS GVF provides data in two different spatial resolutions: global coverage at 4 km resolution and North America coverage (130°E to 30°E, 90°N to 7.5°S) at 1 km

grids. They will be employed to generate a global GVF at 0.009 degree with degraded value apart from the North America region.

VIIRS Global Surface Type (GST) is also taken as an input for emissivity calculation. Updated annually, GST is generated with the 17-type classification scheme of the International Geosphere-Biosphere Program (IGBP) and is produced at a 1-kilometer spatial resolution.

VIIRS reflectance based snow fraction is another important input for LSE product. All the granules of prior day are used to update the snow information for the near-real-time dynamic emissivity. Table 2-1lists the primary derived sensor data used in the LSE algorithm.

1 0 1					
Name	Туре	Source	Description	Dimension	
VIIRS	Dynamic	NDE	VIIRS 4 km global weekly GVF	grid (xsize, ysize)1	
gridded GVF	Dynamic	NDE	VIIRS weekly 1 km GVF for North America	grid (xsize, ysize)2

VIIRS Snow Fraction	Dynamic	NDE	VIIRS reflectance based snow fraction	granule (xsize, ysize)	

Table 2-1 LSE product algorithm input

NDE: S-NPP Data Exploration, DAP: Delivery Algorithm Package

#### 2.2.2 Ancillary data

The background emissivity will serve as ancillary data along with the previous day's gap free snow fraction. For VIIRS LSE, background emissivity contains emissivity and uncertainty of three bands (VIIRS M15, M16 and broadband), plus the background surface type, and for ABI, the background emissivity includes two narrow channels (ABI ch14 and ch15).

LSE is a global product continuous coverage over land surface, however, the snow fraction data may have missing values due to the clouds or darkness. To address this, a gap free snow fraction with latest available snow information is provided here to replace these areas.

To handle the possible exception, GVF and snow fraction monthly climatology are provided as ancillary data. When expected input data for LSE calculation are not available, the climatology data will be utilized.

The following table lists and briefly describes the ancillary data required to generate the LSE.

Table 2-2 LSE product algorithm ancillary input

#### 2.2.3 Look-up tables

In addition to the derived sensor data and the ancillary data, algorithm also requires some look-up tables for algorithm implementation and control. This includes vegetation emissivity (4 narrow channels and 1 broadband) and correction factors for each surface type (17 IGBP classes), the values are listed in Table 2-4. In addition, the snow emissivity and uncertainty for VIIRS/ABI SW channels are also included in the LUT.

#### 2.3 Theoretical Description

#### 2.3.1 Physical Description

Both VIIRS and ABI have the split window channels centered at around 11µm and 12µm for LST retrieval (Table 1-2 and 1-3). To support LST retrievals for these missions, the LSE product includes four narrow bands emissivity: VIIRS M15 & M16and ABI B14 &B15, along with the thermal broadband emissivity, which will be used for LST validation and in the land surface models. LSE product is generated based on the vegetation cover method, in which each pixel assumedly consists of the vegetation and bare ground components. A linear model is used to estimate pixel emissivity based on the vegetation components proportion. To account for the interaction at the structured and rough surfaces, a compensation factor, named cavity term, derived from the geometric model (Caselles and Sobrino 1989), is considered. The effective pixel level emissivity  $\varepsilon_{\lambda}$  could be calculated by:

$$\varepsilon_{\lambda} = \varepsilon_{\lambda}^{bare} \left( 1 - f \right) + \varepsilon_{\lambda}^{veg} f + d\varepsilon_{\lambda} \tag{2-1}$$

where  $\varepsilon_{\lambda}^{\textit{bare}}$  and  $\varepsilon_{\lambda}^{\textit{veg}}$  are the emissivity values of the bare component and vegetation at wavelength of  $\lambda$ , respectively, f is the fraction of vegetation cover and  $d\varepsilon_{\lambda}$  is the cavity term.

In traditional VCM algorithm, both the bare and vegetation component emissivity of each surface type were assigned according to the spectral library data, which works well for the vegetation part with high and stable emissivity. However, soil emissivity could vary from as low as 0.6 to nearly 1 in TIR bands due to the diverse mineral components, soil moisture content, and surface roughness. The simple constant value from the limited spectrum in the spectral library might introduce large uncertainty especially for the arid area with spare vegetation coverage. The high spatial resolution bare component emissivity map with more detailed information could fix this issue. Historical emissivity products, such as ASTER and MODIS, were employed to generate this bare emissivity climatology for this purpose. It should be noted that a conversion between narrow channel emissivities is required from source sensors to target ones.

To account for the seasonal variation, the dynamic surface parameters closely related to the emissivity are introduced to adjust the bare emissivity climatology. In the concept of VCM, the phenology is the predominant factor in the land cover change in most areas so that the near real time fractional vegetation cover is indispensable to produce dynamic emissivity.

Snow with distinct emissivity spectral characters is a common natural phenomenon in the middle and high latitude regions during winter time. The snowfall can dramatically change the LSE and should not be neglected. To improve the data quality, a simple linear model was adopted for the snow effect.

$$\varepsilon_{\lambda} = \varepsilon_{\lambda}^{bv} \left( 1 - f_{SF} \right) + \varepsilon_{\lambda}^{snow} f_{SF} \tag{2-2}$$

where,  $\varepsilon_{\lambda}^{bv}$  is the emissivity after the vegetation adjustment,  $\varepsilon_{\lambda}^{snow}$  is snow component emissivity, and  $f_{SF}$  is the snow cover fraction.

#### 2.3.2 Mathematical Description

#### 2.3.2.1 Bare emissivity climatology

Land surface bare ground can be roughly classified into three types: bare soil, permanent ice & snow, and inland water. Since the emissivity of each type differs from others, the bare emissivity climatology was processed separately with the assistance of the surface type data. Soil covered with/without vegetation constitutes most of the land surface, whose emissivity is the key part of the climatology.

ASTER GED is a mean emissivity database developed by the National Aeronautics and Space Administration's (NASA) Jet Propulsion Laboratory (JPL), California Institute of Technology, from all available clear-sky ASTER data between 2000 and 2008. The version 3 provides a static emissivity of 5 ASTER TIR bands with an average band error of ~1%. This global gridded data was released in 1x1 degree tiles at ~100m and ~1km spatial resolution, respectively (Hulley et al. 2015). The 1km dataset was used to generate bare ground emissivity climatology by reversing equation (2-1):

$$\varepsilon_{AST,bare} = \frac{\varepsilon_{AST} - \varepsilon_{veg} f_{v,AST}}{1 - f_{v,AST}}$$
(2-3)

where  $\varepsilon_{AST}$  is the ASTER GED v3 emissivity,  $\varepsilon_{AST,bare}$  and  $\varepsilon_{veg}$  is the ASTER bare and vegetation component emissivity, and  $f_{v,AST}$  is the ASTER vegetation cover fraction.

In equation (2-3),  $\varepsilon_{_{\!\mathit{veg}}}$  was originally the mean value from ASTER spectral library. However, very low values were found over dense vegetation in GED v3 data, in which pixels with FVC greater than 0.9 have the mean emissivities of 0.972, 0.971, 0.969, 0.974, and 0.974 for the 5 ASTER TIR bands, respectively. Compared with the spectral library value of 0.987, 0.983, 0.979, 0.981 and 0.983, the discrepancy could be up to 0.01, which is significant difference in emissivity. The overestimated  $\varepsilon_{_{\!\mathit{veg}}}$  used in (2-3) may result in an underestimated bare ground emissivity. Therefore, a modification of equation (2-3) is made to use the vegetation component emissivity derived from product instead of that from spectral library. In addition, to address the difference between vegetation types, the vegetation component emissivity was surface type dependent. The result confirms this assumption, i.e. the needle leaf forest has highest emissivity while the savannah is the lowest. There is a difference of almost 0.01 between them.

The bare emissivity climatology derived from ASTER GED v3 covers ASTER 5 TIR bands, which are different from VIIRS and ABI split window bands (Figure 2-3). A linear conversion is constructed to get the channel emissivity  $\varepsilon_i$ 

$$\varepsilon_i = c_0 + c_1 \varepsilon_{10} + c_2 \varepsilon_{11} + c_3 \varepsilon_{12} + c_4 \varepsilon_{13} + c_5 \varepsilon_{14}$$
 (2-4)

where,  $\varepsilon_{10}$ -  $\varepsilon_{14}$  are the five ASTER channel emissivities, and c0 - c5 are the coefficients determined by regression. Since this conversion is designed for the bare soil, a spectral set of soil, rocks and a few construction material including asphalt and concrete were selected from ASTER spectral library for the regression. Both the source and target channel emissivity were convoluted with their corresponding spectral response function. The coefficients were summarized in Table 2-3. Considering the correlation between source and target channels, the 11 $\mu$ m channel was just calculated by ASTER B13 and B14. Although it's difficult to convert the emissivity of 12 $\mu$ m band due to little overlap with ASTER bands, the correlation with adjacent bands emissivity for a certain type is good enough to get an acceptable conversion. Previous studies have shown that 8 - 13.5 $\mu$ m spectral domain could represent the broadband emissivity best, and the BBE could be modeled using ASTER narrow TIR bands (Cheng et al. 2013).

Table 2-3 Coefficients of the spectral conversion equation

Permanent snow and ice occupies a large area at polar region, however, there are no ASTER GED data at Antarctic areas. Besides the permanently covered snow and ice at northern hemisphere have a much lower emissivity than the spectral library value. Current data also indicated snow and ice emissivity vary in types, e.g., generally ice and coarse snow have lower emissivity than fine or fresh snow (Salisbury et al. 1994). An alternative emissivity product is required to map snow emissivity, rather than the mean library data. University of Wisconsin Global Infrared Land Surface Emissivity Database (UWIREMIS) database is derived from MODIS emissivity product could extend to high resolution emissivity spectra 3.6 and 14.3 microns and serves the need well. Using the same method for ASTER GED, UWIREMIS mean emissivities at 10 channels were generated from the monthly data between 2003 and 2014. A high spectral resolution algorithm was employed to generate finer resolution data, which was then convoluted to the emissivity of VIIRS, ABI SW bands and 8 - 13.5µm broadband. Compared with ASTER GED, corresponding channel emissivity derived from MODIS mean emissivity works better over the snow area

February 2025

as Figure 2-4 shows, in which the MODIS derived snow emissivity have better agreement with the spectral library.

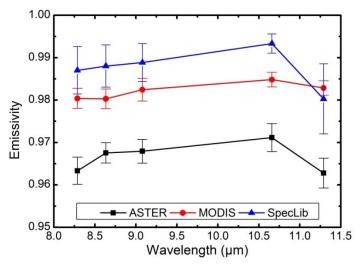

Figure 2-4 Snow/Ice emissivities of MODIS, ASTER GED, and spectral library at ASTER TIR channels

Based on the analysis above, climatology of the permanent snow and ice area is replaced by the mean value derived from UWIREMIS after re-sampling from 0.05 degree to 0.009 degree. Given the high homogeneity of snow area, this procedure will not introduce significant uncertainty.

For the third type, namely inland water is always regarded as black body for its high emissivity. ASTER emissivity product (using the TES algorithm) might not work very well at the surface with low-contrast spectral, which has been reported in (Wang et al., 2019), therefore the average value from spectral library was used according to the surface type data. Additionally, once the water gets frozen at high latitude area, the ice emissivity will be used instead, which is much lower than that of water.

It should be noted that there are nearly 1% pixels with either missing values or unreasonable values (larger than 1 or less than 0.6) in ASTER GED dataset due to cloud contamination, spatial coverage, or inversion issues. These were replaced by the mean value of adjacent available pixels with the same surface type. The effective radius was set as 2.5 degree. If there are no enough available pixels, a global mean value of that surface type will be used.

An example of the global gridded background emissivity climatology was shown in Figure 2-5.

#### VIIRS M15 Background Emissivity

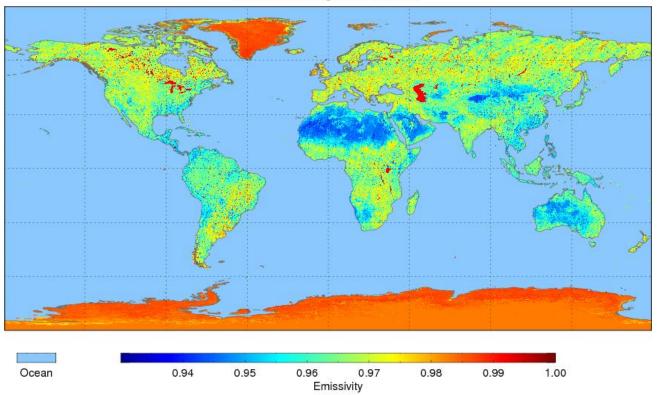

Figure 2-5 VIIRS M15 background emissivity

#### 2.3.2.2 Dynamic emissivity

Based on the bare ground emissivity climatology, the real time vegetation fraction data was used to adjust the emissivity via equation (2-1), in which the bare ground climatology works as the soil component emissivity, while the vegetation one was assigned according to the spectral library. The cavity term is defined below

$$d\varepsilon_{\lambda} = 4\langle d\varepsilon_{\lambda} \rangle f(1-f) \tag{2-5}$$

where  $\langle d\varepsilon_{\lambda} \rangle$  is the maximum cavity effect value, which is assumed to exist under nadir observation and can be simplified as

$$\langle d\varepsilon_{\lambda} \rangle = (1 - \varepsilon_{\lambda}^{bare}) \varepsilon_{\lambda}^{veg} F(1 - f)$$
 (2-6)

where, F is the shape factor in the "box model" depending on the vegetation height and separation.

Both the vegetation component emissivity and cavity term depend on surface type and will be estimated based on the IGBP database. The vegetation emissivity for each type is determined according to the scheme of assignment of library samples outlined in (Trigo et al. 2008), which was designed for SEVIRI. The detailed values for each surface type are shown in Table 2-4

Table 2-4 Mean vegetation emissivity and cavity term for each surface type

To implement the vegetation adjustment, near real-time vegetation fraction product is required. VIIRS GVF operational product developed by the NOAA/NESDIS Center for Satellite Applications and Research (STAR) is produced as a daily rolling weekly composite at 1 km resolution. This GVF product derived from enhanced vegetation index with a relative uncertainty level of around 12%. It should be noted that its data latency is one day after the 7-day compositing period. Such delay is considered acceptable for emissivity modeling, as the growth of plants is a relatively slow process.

Currently, the 1-km VIIRS GVF is available for sub-region (130°E to 30°E, 90°N to 7.5°S) while the global one is at 4-km resolution. Therefore the global (4 km) and regional (1 km) weekly GVF data are used to generate a composite intermediate output of GVF at 1 km. The 1 km global GVF will be produced in the near future to replace the degraded one.

To model the snow cover impact on emissivity, snow fraction product is used in the algorithm as described by (2-2). An operational VIIRS snow fraction product generated by NOAA/STAR is used here, which uses the reflectance of VIIRS visible band I1 (0.6-0.68µm) and applies a linear unmixing technique to empirically determine the snow portion (Romanov et al. 2003). In the operational processing, the gridded snow fraction of all granules data from the previous day is needed to make the composition, leading to one-day latency. The daily gap-free snow fraction will be retained for at least 14 days for future processing. For the daily composited snow fraction, the gaps resulting from clouds, darkness at pole regions or any other reason will be replaced by the most recently available retained values. This approach might introduce uncertainty, particularly during heavy snowfall events. A quality flag will be set to mark these pixels as non-instantaneous input for further diagnostics.

#### 2.4 Algorithm Output

The output of the VIIRS LSE algorithm includes four data arrays: three channels' LSE values and associated quality control flags, while ABI LSE includes three datasets (Table 2-5). The LSE is scaled to a one-byte signed integer dataset, with a scale factor of 0.001 and an add offset of 0.9. The valid emissivity range for these channels is from 0.8 to 1. The final data is stored in a NetCDF file at global 1 km coverage.

The quality flag is designed as a one-byte field, including two bits for overall quality, stratified into four quality levels based on theoretical uncertainty estimation (see 2.5.3 for details). The next two bits represent four surface types (land, permanent snow/ice, ocean, and inland water), which are algorithm-related as discussed in the previous section. Bit 4 is the GVF flag, indicating whether it represents the true 1 km GVF or the downscaled GVF from 4 km data. Bit 5 marks the data as either instantaneous snow or using previous snow information. This quality flag is applicable to both VIIRS and ABI (Tables 2-6).

The LSE product includes comprehensive metadata that details its features and specifications. This metadata encompasses general information such as the product's creation date and time, the distributor, version ID, short name, and platform short name. It also contains global statistics, such as the average LSE for each band and the percentage distribution across quality levels (high, good, median, bad). Additionally, the metadata provides information on input data, including the date and source of the GVF, snow basemap, and snow fraction.

#### 2.5 Performance Estimates

#### 2.5.1 Test Data Description

Unit Tests have been conducted to verify whether LSE is correctly implemented in the NDE system. Dataset from three seasons (20170109, 20170409 and 20170709) with a wide range of vegetation and snow fraction have been selected for product verification. These datasets include the static input data designed for LSE algorithm, which have been introduced in section 2.2, such as background emissivity climatology, VIIRS annual surface type and the look-up tables. For these certain days, dynamic input data are prepared for test as follows:

- Daily rolling weekly GVF data Global 4 km and North America regional 1 km. s20170103 e20170109, s20170403 e20170409, s20170703 e20170709
- VIIRS snow fraction EDR: all granules of 20170109, 20170409 and 20170709
- Previous day (Day-1) global gridded gap free snow fraction: 20170108, 20170408 and 20170708

Eventually, daily LSE products of these days are produced, as Figure 2-6 shows.

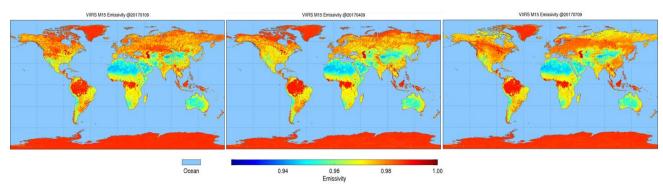

Figure 2-6 LSE product verification dataset

Although the in-situ emissivity measurement is still a challenge and is very limited, it is the most effective and reliable dataset for algorithm validation. The primary ground emissivity dataset was collected in northwest China in 2012 under the context of Heihe Watershed Allied Telemetry Experimental Research (HiWATER). The corresponding satellite LSEs are produced corresponding to the ground observation time. Four barren sites measurements were obtained on July 10, 2012 and three observations at different growing stages (20120530, 20120615 and 20120624) were made over a vegetation site. Besides, performance of long time LST derived from LSE are also used to evaluate the product.

#### 2.5.2 Sensor Effects

LSE product is generated based on VIIRS EDR as well as historical emissivity climatology rather than directly retrieved from sensor data record (SDR). Sensor effects such as its random noise, calibration error and geolocation uncertainty will indirectly impact LSE accuracy through the retrieval error of VIIRS GVF, snow fraction and surface type. More detailed information about the errors of these products can be found from the related algorithm theoretical basis documents, while their impact on LSE will be characterized in the following section.

#### 2.5.3 Retrieval Errors

To quantify the uncertainty in the emissivity product, the theoretical emissivity error is calculated based on the error propagation theory. LSE retrieval error budget contains three uncertainty sources: the bare ground emissivity uncertainty, GVF error and VCM method uncertainty, snow fraction error and linear mixing uncertainty.

The bare ground climatology uncertainty largely depends on the quality of ASTER GED. ASTER GED is mean value of clear sky emissivity product retrieved using TES algorithm after an enhanced atmospheric correction named water vapor scaling method. The uncertainty has been quantified through the temperature and emissivity uncertainty simulator (Hulley et al. 2012), in which the band-dependent emissivity error is quantified as a function of the total column water for three surface types (bare, gray body and the transition). Besides, the emissivity conversion between ASTER and VIIRS/ABI channels will also introduce uncertainty, especially for the 12 µm bands due to the less overlap with ASTER. All these uncertainties are assumed to be independent. The combined error could be calculated using (2-7).

$$\delta \varepsilon = \sqrt{\sum_{i=1}^{n} (\delta \varepsilon_i)^2}$$
 (2-7)

For the dynamic emissivity, the errors of GVF and snow fraction contribute to the product uncertainty along with the climatology. The uncertainty of VCM could be described as (2-8)

$$\delta \varepsilon_{VCM} = f_{v} \delta \varepsilon_{v} + (1 - f_{v}) \delta \varepsilon_{g} + 4 f_{v} (1 - f_{v}) \delta \langle d\varepsilon \rangle + \left[ \varepsilon_{v} - \varepsilon_{g} + 4 \langle d\varepsilon \rangle (1 - 2 f_{v}) \right] \delta f_{v}$$
 (2-8)

where,  $\delta \varepsilon_{g}$  is the bare ground emissivity uncertainty mentioned above,  $\delta \varepsilon_{v}$  is the vegetation emissivity uncertainty, using the standard deviation of the emissivity from the spectral library,  $\delta f_{v}$  is the GVF product error.

Similar to the GVF, the uncertainty brought during the snow effect calculation could be calculated as (2-9)

$$\delta \varepsilon = f_s \delta \varepsilon_{VCM} + (1 - f_s) \delta \varepsilon_s + (\varepsilon_s - \varepsilon_{VCM}) \delta f_s$$
 (2-9)

Where,  $\delta \varepsilon_{VCM}$  is result of (2-8), and  $\delta \varepsilon_s$  is snow emissivity uncertainty from the spectral library, and  $\delta f_s$  represents the snow fraction product uncertainty.

The mean emissivity errors of the split window channels are grouped into four bins: [0, 0.005], [0.005, 0.010], [0.010, 0.015] and 0.015 beyond. Figure 2-7 shows a case on 20170409, in which the emissivity uncertainty shows a global distribution of 1.17%, 75.91%, 22.88% and 0.04% for each category.

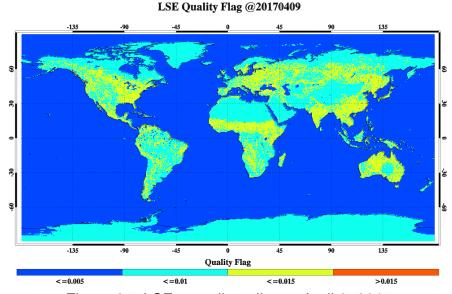

Figure 2-7 LSE overall quality on April 9, 2017

#### 2.6 Practical Considerations

#### 2.6.1 Numerical Computation Considerations

The LSE product is developed using a semi-empirical algorithm with basic mathematical routines, which are robust and computationally efficient. For storage consideration, LSE

February 2025 18

values are scaled to signed byte, with scale factor and offset defined in the attributes. Quality flags for each pixel value should be bit-flag definitions, to minimize data storage.

#### 2.6.2 Programming and Procedural Considerations

The simplicity of the algorithms described in this document is translated into small amount of code using basic mathematical routines. Due to its large size, stemming from global coverage and high spatial resolution, the 1 km global daily LSE data is partitioned into smaller segments to enhance computing efficiency.

#### 2.6.3 Quality Assessment and Diagnostics

The LSE overall quality flags are designed according to the system requirement. And a couple of parameters and indicators are reported as retrieval diagnostic flags, for example, the GVF resolution and latency flag of snow fraction help to diagnose the data quality. The lists of quality flags as well as their detailed descriptions are given in section 2.4.

Statistical information is also included in the product, *e.g.*, the minimum and maximum value, each quality group percentage etc.

#### 2.6.4 Exception Handling

The algorithm will handle exceptions by input/output data check and quality flags. LSE is designed as a gap-free global product. When generating the bare ground emissivity climatology, the missing value and pixel with poor quality will be replaced by the interpolated value.

If there is no GVF data available for certain day; the most recent one will be used. Once the latency is longer than 15 days, the monthly GVF climatology will be employed instead. This climatology is the mean value of each month, generated using all the SNPP/VIIRS daily rolling weekly GVF from 2013 to 2017.

For the snow fraction, there are two types of input data: the VIIRS granule snow fraction and the previous gridded data used for gap filling. If they do not exist, the most recently available one will be used. Similar to the GVF, if there is no data within 15 days, the monthly snow fraction climatology will be used instead. The monthly snow climatology is generated using SNPP/VIIRS snow fraction from 2014 to 2017.

#### 2.7 Validation

#### 2.7.1 LSE validation

A series of in situ emissivity measurements were carried out in northwest China in 2012 under the context of Heihe Watershed Allied Telemetry Experimental Research (HiWATER) (Li et al. 2013). Ground emissivity was collected at four barren sites for once

February 2025

and cropland areas at three different growing stages. Four large homogeneous sites located in the arid area were chosen for LSE evaluation. There are three typical surface types in this region including the gobi site (GB), desert site (SSW) and two desert steppe sites (HZZ, JCHM), as Figure 2-8 shows.

The emissivity was acquired by an ABB BOMEM MR304 Fourier Transform Infrared Spectroscopy which is a high-precision instrument with a spectral resolution of up to 1cm<sup>-1</sup> in 2-15 µm range. Under field conditions, the targets and downward sky radiance was measured using the MR304 and a diffuse golden plate and the emissivity was retrieved by the Iterative Spectrally Smooth Temperature and Emissivity Separation (ISSTES) algorithm, with an accuracy better than 0.01(Wang et al. 2015). The LSE data derived from the product was compared with the field measured emissivity spectra convolved with the spectral response function of VIIRS and ABI SW bands. The results indicate that LSE algorithm works well for these bare surfaces with pretty good agreement within 0.006 for narrow bands and 0.012 for broadband.

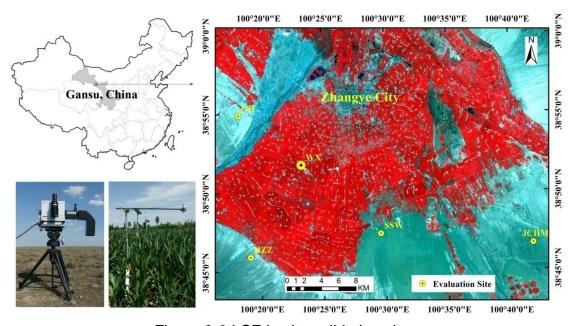

Figure 2-8 LSE in situ validation sites

To evaluate the dynamic emissivity, a corn field (WX) located in the artificial oasis was selected to evaluate the vegetated area with various GVF levels. To facilitate measurement over the canopy, a more compact multichannel thermal infrared radiometer (CE312-2) equipped with five narrow bands (8.25-8.60, 8.49-8.86, 8.95-9.34, 10.16-10.96, 10.86-11.71µm) and a broadband channel (8.01-13.34µm) was used. This radiometer has a field view of 10° and was mounted at least 1 meter above the top of canopy to collect the radiation from the mixed scenes. Five narrow band emissivities along with LST were retrieved using ASTER TES algorithm; subsequently, the broadband

Version 1.4

February 2025 20

emissivity could be determined through the Planck function using the retrieved LST from the TES algorithm. Since CE312-2 is a multichannel radiometer with similar channel as ASTER, it could not be directly compared with the VIIRS and ABI emissivity product. Considering that the product is derived from ASTER GED, an alternative approach to evaluate the dynamic emissivity is to produce emissivity of ASTER 5 TIR channels using the current algorithm. The result shows LSE product works well at this site with a mean accuracy of ~0.007 for ASTER channels.

#### 2.7.2 Evaluating LSE in LST retrieval

Currently, LSE field measurement is still a challenge. In situ measurements are still limited and long-term LSE monitoring using ground data is nearly impossible. LSE product is proposed primarily for LST retrieval, in which LSE accuracy will significantly impact the LST quality. What's more, there are long-term LST ground measurements available for evaluation, so LST retrieval accuracy could be regarded as an alternative criterion for LSE quality. To evaluate the LST accuracy, the temperature based method was adopted, which involves direct comparison with ground measurements performed at the thermally homogenous sites concurrent with the satellite overpass.

The SURFace RADiation budget observing network (SURFRAD) provides high quality long-term measurements of surface upwelling and downwelling long wave radiations along with other meteorological parameters (Augustine et al. 2000, 2005). There are seven sites available for the LST validation. Each station is equipped with a pyranometer on a 10 meter high tower with a field-of-view approximate70 m × 70 m. SURFRAD observations from February 2012 to July 2015 are used for validation of the VIIRS LST retrieval.

The spectral emissivity data has been applied to a variety of emissivity-explicit LST algorithms including the VIIRS enterprise LST algorithm. The derived LSTs have been evaluated against in situ measurements and show promising quality.

These validation activities mentioned above are preliminary results, more substantial algorithm and product validations are necessary.

#### 3 ASSUMPTIONS AND LIMITATIONS

#### 3.1 Performance Assumptions

The following assumptions have been made in the LSE algorithm development and quality evaluations.

- The basic assumption of VCM is that land surface pixels contain two components: bare ground and vegetation and emissivities of the two components do not change over time. Vegetation emissivity and 3-D structure are surface type dependent, thus each IGBP class has same vegetation emissivity and cavity correction factors.
- Weekly composited GVF data after noise filtering is available and vegetation fraction doesn't have dramatic change during one week.
- Permanent snow/ice emissivity is homogenous at 0.05x0.05 degree grids, thus degraded MODIS snow emissivity at 5km resolution will not introduce significant uncertainty. Since there is no data in the area under polar night, we assume snow fraction will not change during the darkness period.

Based on the assumptions mentioned above, LSE product has its limitations:

- Currently, the emissivity is designed for nadir viewing direction only, without consideration of the angular effect of emissivity.
- GVF and snow fraction are the only two factors controlling the variation of emissivity.
   Soil moisture has not been considered in the current algorithm, which will result in a constant value for barren area without vegetation and snow present.
- Snow fraction data has at least one day latency, the pixels with new significant snowfall might have larger uncertainty due to lack of instantaneous data.

#### 3.2 Potential Improvements

Soil moisture has proved to have significant impact on emissivity. However, bare ground emissivity as a static value in LSE algorithm made great contribution at low GVF areas. While this is acceptable for arid areas with extremely low soil moisture, it might introduce large uncertainty at the sparse vegetation area with large soil moisture fluctuations. A potential improvement in the future will be soil moisture correction, which will improve the LSE quality over low GVF area.

For the validation part, ground measurements are still very limited, and more in-situ emissivity from different areas could be collected through international collaborations, which will highly support LSE product.
